

The BlueGene/L Supercomputer*

Gyan Bhanot^a, Dong Chen^a, Alan Gara^a and Pavlos Vranas^a

^aIBM T.J. Watson Research Center, Yorktown Heights, NY 10598, USA

The architecture of the BlueGene/L massively parallel supercomputer is described. Each computing node consists of a single compute ASIC plus 256 MB of external memory. The compute ASIC integrates two 700 MHz PowerPC 440 integer CPU cores, two 2.8 Gflops floating point units, 4 MB of embedded DRAM as cache, a memory controller for external memory, six 1.4 Gbit/s bi-directional ports for a 3-dimensional torus network connection, three 2.8 Gbit/s bi-directional ports for connecting to a global tree network and a Gigabit Ethernet for I/O. 65,536 of such nodes are connected into a 3-d torus with a geometry of $32 \times 32 \times 64$. The total peak performance of the system is 360 Teraflops and the total amount of memory is 16 TeraBytes.

1. INTRODUCTION

IBM has previously announced a multi-year initiative to build a petaflops scale supercomputer for computational biology research [1]. The BlueGene/L machine is a first step in this program [2]. It is based on a different and more general architecture than the original BlueGene announcement. In particular, BlueGene/L uses embedded PowerPC processor cores developed by IBM Microelectronics [3] for ASIC products.

The lattice community has seen great success of some special-purpose, massively parallel machines dedicated for QCD, for example, the combined 1 Teraflops QCDSM machine [4] and the follow-on 20 Teraflops QCDOC machine [5] currently being developed at Columbia University in collaboration with IBM Research.

The BlueGene/L design philosophy has been influenced by QCDSM and QCDOC. Contrasting to the current commercial approach of building large-scale supercomputers by clustering general purpose yet complex SMP systems, BG/L leverages IBM's system-on-a-chip silicon technology and builds a large parallel system consisting of more than 65,000 nodes, yet at a significantly lower price/performance and power consumption/performance versus conventional approaches. Compared to QCDOC, BG/L will be using a newer generation of IBM's silicon tech-

nology, with enhancements in single node performance as well as a more general network supporting hardware point-to-point message passing (cut-through routing). This makes BG/L suitable for a wide variety of applications.

The BlueGene/L project is a jointly funded research partnership between IBM and the Lawrence Livermore National Laboratory (LLNL) as part of the US Department of Energy ASCI Advanced Architecture Research Program. The main research and development effort is centered at the IBM T.J. Watson Research Center, with supports from IBM Enterprise Server Group and IBM Microelectronics. Application performance and scaling studies have been initiated with partners at a number of academic and government institutions, including the San Diego Supercomputing Center and the California Institute of Technology.

A large machine with a peak performance of 360 Teraflops is anticipated to be built at the LLNL in the 2004-2005 time frame. A smaller, 100 Teraflops machine is expected to be built at the IBM T.J. Watson Research Center for computational biology studies.

2. BG/L OVERVIEW

BlueGene/L is a massively parallel, scalable system. A single parallel job can use up to 65,536 compute nodes. The system is configured as a

*Talk presented by D. Chen.

Figure 1. Building BlueGene/L. A node ASIC contains 2 CPUs. 2 node ASICs along with their associated local external memory are built onto a compute card. A node board contains 16 compute cards. 32 node boards are then plugged into both sides of 2 mid-plane boards in a cabinet. A large BG/L system contains 64 cabinets, forming a $32 \times 32 \times 64$ torus of compute nodes, with a peak performance of 180/360 Tflops.

$32 \times 32 \times 64$ three-dimensional torus of compute nodes. Each node consists of a single compute ASIC and memory. Each node can support up to 2 GB of local memory. Balancing cost and application requirements, our current plan calls for 256 MB of DDR-SDRAM per node.

The ASIC will be manufactured on IBM CMOS CU-11 0.13 micron copper technology with an expected 11.1 mm^2 die size. This is the next generation IBM CMOS technology compared to the one used by QCDQC. There are two PowerPC 440 32 bit integer CPU cores in each BG/L ASIC, each core connects to a “double” floating point unit capable of 2 fused floating point multiplies per CPU clock cycle. At a target frequency of 700 MHz, each core can achieve a peak performance of 2.8 Gflops. In normal operations, we expect that one CPU will be mainly doing compu-

tation while the other one will be busy handling communications. However, for certain kinds of applications, if the communication requirement are small compared to the amount of compute, or if there are separate computation and communication steps, then both cores can be utilized for compute, leading to 5.6 Gflops peak performance per node. We therefore quote the performance per node as 2.8/5.6 Gflops.

Figure 1 shows the steps of building the BlueGene/L supercomputer. 2 compute ASIC chips along with their associated local memory are put onto a compute card. A node board will have 16 compute cards. A cabinet includes 2 mid-planes. A total of 32 node boards are plugged into both sides of the 2 mid-planes. Within a cabinet, the compute nodes form a geometry of $8 \times 8 \times 16$ ($8 \times 8 \times 8$ per mid-plane) with a peak per-

formance of 2.9/5.7 Tflops and a total of 256 GB memory. The BlueGene/L system consists of 64 cabinets connected as a $32 \times 32 \times 64$ torus. The total peak performance is 180/360 Tflops and the total amount of memory is 16 TB. The system will occupy an area of about $250 m^2$, and the total power is estimated at approximately 1 MW.

In addition to the computing nodes in the system, there are also I/O nodes. Each I/O node contains the same ASIC as in a compute node, but with 512 MB of memory. These additional I/O cards are plugged into the same node board with compute cards. An I/O node connects to a number of compute nodes through a custom high speed network, and to outside host and disk farm through a Gigabit Ethernet. These I/O nodes are used to offload the work required for disk I/O and host communications from the compute nodes. We plan to install one I/O node per 64 compute nodes. The maximum ratio is one I/O node for every 8 compute nodes.

Besides the active 64 cabinets, the large BG/L system also includes a number of spare cabinets, Gigabit Ethernet switches racks, disk I/O racks plus a host computer. The Gigabit switches connect to the BG/L I/O nodes, the host computer and the disk farm.

3. BG/L ARCHITECTURE

The architecture of the BG/L node ASIC is shown in Figure 2. Each ASIC integrates two PowerPC 440 cores, each with a PowerPC 440 FP2 core, 2 small L2 buffers, 4 MB embedded DRAM configured as L3 cache, DDR-SDRAM memory controller for connecting to external memory, custom designed high speed torus and tree network logic, a Gigabit Ethernet and a JTAG control interface.

3.1. PowerPC core

The 440 is a standard 32-bit integer microprocessor core product from IBM Microelectronics. The same core for a previous generation technology is used in the QCDOC project. Each core has 32 general purpose registers. It has integrated 32 KB instruction L1 cache and 32 KB data L1 cache. They provide one cycle access from the

CPU. There are three 128 bit buses coming out of the core, one each dedicated for data read, data write and instruction load. This core supports all common PowerPC instructions as well as instructions defined in the PowerPC Book E standard for embedded processors.

The 440 FP2 core is an enhanced “double” 64-bit floating-point unit. It consists of a primary and a secondary unit, each of which is a complete FPU with their own register sets. The primary FPU supports standard PowerPC floating point instructions. It can do a single fused 64 bit multiply-add in one processor cycle. Through a SIMD like instruction extension, both FPU units can be utilized to execute 2 fused 64 bit multiply-adds per cycle. In addition, a separate floating point load/store operation can be executed in parallel to the multiply-adds. The load/store unit supports 128 bit “quad-word” load/store from either the L1 cache or the 440 memory interface, to a pair of registers, one each from the two FP units. This increased load/store bandwidth to FP registers is to match the increased floating point performance. It is also used to efficiently move data to and from the custom high-speed network interfaces, as the 32 bit integer unit does not have the adequate bandwidth to its internal registers to support high speed data movements. The floating point instruction extension is also powerful enough to allow the exchange of register contents between the two FP units while they are executing multiply-adds, without extra instruction overheads.

3.2. Memory Subsystem

Each of the 440 processor core is directly connected to a small 2KB L2 cache, then to a shared L3 directory which controls 4 MB of embedded DRAM as the L3 cache. The L3 controller directly connects to a DDR-SDRAM controller for external memory. Both the 4 MB L3 cache and the external DDR-SDRAM are ECC protected.

Because the 440 hardware does not support SMP protocols for its L1 cache, the L1 cache of the two processors are not coherent. We have therefore implemented a lock box and a small fast multi-port SRAM behind the two L2 caches to facilitate processor-to-processor communications.

Figure 2. BlueGene/L node ASIC. Each ASIC integrates two 32 bit PowerPC 440 integer CPU cores, 2 “double” floating point FP2 cores, L2 cache buffers, 4 MB EDRAM as L3 cache, DDR-SDRAM controller for external memory, high speed torus network logic, global tree network logic, Gigabit Ethernet and JTAG control interface.

The L2 and L3 caches are coherent for both processors.

A data prefetch engine is built into each L2 cache to reduce the latency for sequential data accesses from L3 and external memory. The memory subsystem is being designed for low latency, high bandwidth accesses to cache and memory. An L2 hit returns in 6 to 10 processors cycles, an L3 hit in about 25 cycles, and an L3 miss (loading from external DRAM) in about 75 cycles. Various memory bandwidth numbers are listed in Table 1 as they are compared to QCDOC.

The L2 caches are also directly connected to a set of FIFOs to allow for fast and high bandwidth access to both a 3-d torus network and a global tree network.

3.3. 3-D Torus Network

The 3-d torus is a high speed network used for general-purpose, point-to-point message passing

operations. Each ASIC has 6 torus links build in. On a compute node, these 6 links are connected to its 6 nearest neighbors, in the $+x$, $-x$, $+y$, $-y$, $+z$ and $-z$ directions, respectively. There is one link between a pair of nearest neighbors. Each link is a bi-directional serial connection with a target speed of 1.4 Gbit/s per direction.

Figure 3 illustrates the torus logic. Within a node ASIC, 2 sets of injection FIFOs and 2 sets of reception FIFOs are directly connected to the L2 cache. These FIFOs along with 6 input links and 6 output links are then connected through a global cross-bar switch. A packet injected on one node will route through the 3-d torus network in hardware without any software overhead until it reaches its destination, where it will then be pulled out by a CPU from a reception FIFO. A packet could vary in size from 32 bytes to 256 bytes in 32-byte granularity. Even though in

Figure 4. Adaptive routing of the torus network. A packet could take different routes to reach its destination.

Virtual channels are used to in the torus network to avoid dead-locks [6]. A token based flow control mechanism is used to improve throughput

[7]. The torus switch is highly pipelined and implements virtual cut-through routing [8]. In addition, the torus network supports both adaptive and deterministic minimal-path routing [9,10]. Figure 4 illustrates adaptive routing. Packets could take different paths to reach their destination as long as the paths are minimal, i.e., every hop a packet makes should reduce its distance to the destination. The actual path a packet goes through is determined dynamically on each node depending on local traffic. All these features combined optimize both the throughput and latency over the torus network.

In addition to the point-to-point message passing, we have also implemented multicast operations in the torus hardware to allow for one node to broadcast a message to a “class” of nodes. This feature has been proven to be very useful for a number of applications.

All data and token flow-control packets are protected by CRC. If an error happens on a link, the bad packet that got received will be automatically deleted from the network, and the good packet will be retransmitted over the same link. The error and retransmission protocol is handled automatically by the torus hardware.

3.4. Global Tree Network

On a large scale parallel machine like Blue-Gene/L, one constraint that affects the scalability of a large class of applications is the time it takes for a global reduction operation, for example, a global sum.

To reduce the latency of global reduction operations, the BG/L supercomputer implements a global tree network. This is a binary-tree like network shown in Figure 5. The global tree network supports global broadcast from a single node to all nodes, and global reduction operations including global integer maximum, global integer sum and certain binary operations like global AND, OR and XOR. The tree network logic is also integrated into the node ASIC.

During a global reduction, each node contributes a message. All messages from all nodes are combined into a single message and are then broadcast to each contributing nodes. A single round-trip latency on the global tree network is

Figure 6. Illustration of partitioning of BG/L. A cabinet of nodes can either be connected in a torus loop, or be jumped over where the cabinet will form its own torus in a separate physical partition.

Figure 6 illustrates the basic idea of BG/L partitioning. Within a BG/L cabinet, there are 2 mid-planes, each with 512 compute nodes attached forming a $8 \times 8 \times 8$ 3-d lattice. On the edge of each mid-plane, there is a set of re-drive chips. They capture the high speed torus and tree network signals coming from node ASICs over a certain length of mid-plane board trace, then re-drive them over the cable connecting different cabinets. This improves the high speed signal quality. These re-drive chips can be programmed by the host to either include the nodes of the current cabinet in the torus loop for a large partition, or to skip over them, therefore creating a separate physical partition.

This scheme allows each partition to be electrically isolated. Each partition has its own torus and tree networks that do not communicate with other partitions. With a few more spare cabinets

Figure 7. BlueGene/L system expected to be built at the LLNL.

4. SOFTWARE

Scalable system software that supports efficient execution of parallel applications is an integral part of the BlueGene/L architecture. Our plan is to have a lightweight high-performance kernel running on compute nodes, and to expect Linux running on I/O nodes. The lightweight compute kernel approach was motivated by the Puma and

Cougar kernels at Sandia National Laboratory and the University of New Mexico.

The BG/L compute kernel is a single user OS that supports execution of a single dual-threaded (one thread for each of the two processors within a node) user process. It provides a single and static virtual address space to the one running compute process. There is no need for context switching. Because the PowerPC 440 processor core supports large pages, demand paging is not necessary. The user process will receive full resource utilization, yet the OS is still protected from the user application through a virtual memory system.

I/O nodes will support multiple processes. They will only execute system software, no user applications. They provide I/O support to compute nodes, i.e., file operations to the disk farm, control and monitoring support for the host, etc.

In terms of development tools and environment, IBM's XL-C, XL-C++ and XL-FORTRAN compilers are expected to be ported to support both the PPC 440 integer unit as well as the FP2 floating point unit. The GNU-C compiler already supports the common set of PowerPC instructions, albeit it does not support the FP2 instruction extensions, which the IBM compilers are expected to support. A set of highly optimized math libraries is also expected to be provided to facilitate high performance application development. As for parallel environment, we anticipate to provide MPI support as well as a user level, low latency system programming interface to facilitate the utilization of the high speed torus and tree networks.

5. APPLICATIONS

The BG/L team has been doing extensive studies of a wide variety of applications [11]. The results of these studies are very encouraging. They show that a large class of applications scales well on the BG/L architecture, even to the level of 65,536 nodes.

In this section, for the interest of the lattice community, we will compare the architecture of BG/L to QCDOC, as applied to QCD type applications. Reference [13] shows that for Wilson

fermions, on a 2^4 lattice per node, QCDOC can sustain about 50% of the peak performance.

Table 1
Comparisons between QCDOC and BlueGene/L.

	QCDOC	BlueGene/L
CMOS Technology	0.18 μm	0.13 μm
CPU	500 MHz	700 MHz $\times 2$
EDRAM size	4 MB	4 MB
Peak flops/node	1 Gflops	5.6 Gflops
Network Topology	6-d torus	3-d torus
Bandwidth:		
L1 cache to FPU	4 GB/s	22.4 GB/s
CPU interface peak	8 GB/s	11.2 GB/s
CPU read sustained	3 GB/s	8.4 GB/s
EDRAM interface	16 GB/s	22.4 GB/s
External DRAM	2.6 GB/s	5.6 GB/s
Torus/link	0.5 Gbit/s	1.4 Gbit/s

Table 1 shows a comparison of various performance and memory bandwidth numbers between QCDOC and BG/L. For Lattice QCD applications, because most of the communications are between nearest neighbors, we expect that both processors on a BG/L node will be available for computation. From QCDOC to BG/L on a per node basis, the sustained memory read bandwidth from EDRAM improves by a factor of 2.8, the external memory bandwidth by a factor of 2.15 and the torus network bandwidth by a factor of 2.8. While the peak floating performance is increased from 1 Gflops to 5.6 Gflops, we expect the overall performance improvement per node will be determined mainly by the memory bandwidth, therefore about a factor 2.15 to 2.8. Given the high efficiency of QCDOC, we expect BG/L to also perform well for QCD applications.

6. CONCLUSION

System-on-a-chip technology has opened new possibilities of building large scale supercomputers. By optimizing the overall system, great reduction in cost/performance, power consumption/performance and machine size/performance can be achieved.

BlueGene/L is a first step in IBM's commitment to petaflops scale computing by exploring a new architecture of building massively parallel machines. With more applications ported and optimized for this kind of architecture, there will be great scientific benefits and rewards.
